Fluorescent guanosine analogs (excitation at 340 nm, emission at 450 nm) are incorporated into oligonucleotides through a native deoxyribose linkage using automated DNA synthesis which allows them to base stack with native bases. As a result, slight changes in DNA structure can cause significant changes in spectral properties. These compounds are highly fluorescent as monomers in solution, but lose intensity in oligonucleotides. The use of these fluorophores as hairpin hybridization probes is based on the dramatic fluorescence increase that occurs upon them being squeezed out of the strand during annealing where the probe has not been provided with a base-pairing partner in the complementary strand. The degree of increase depends on the oligonucleotide sequence and the annealing strands' concentration. It allows the detection of specific DNA sequences in a mixture without separation of annealed and labeled products. These stable probes are treated as normal phosphoramidites during the DNA synthesis and subsequent de-blocking procedures.
